Linearizability of Persistent Memory Objects 
Under a Full-System-Crash Failure Model

Abstract. This paper provides a theoretical and practical framework
for crash-resilient data structures on a machine with persistent (non-
volatile) memory but transient registers and cache. In contrast to certain
prior work, but in keeping with “real world” systems, we assume a
full-system failure model, in which all transient state (of all processes)
is lost on a crash. We introduce the notion of durable linearizability
to govern the safety of concurrent objects under this failure model and a
responding relaxed, buffered variant which ensures that the persistent
state in the event of a crash is consistent but not necessarily up to date.

At the implementation level, we present a new “memory persistency
model,” explicit epoch persistency, that builds upon and generalizes prior
work. Our model captures both hardware buffering and fully relaxed con-
sistency, and subsumes both existing and proposed instruction set ar-
chitectures. Using the persistency model, we present an automated trans-
form to convert any linearizable, nonblocking concurrent object into one
that is also durably linearizable. We also present a design pattern, analo-
gous to linearization points, for the construction of other, more optimized
objects. Finally, we discuss generic optimizations that may improve per-
formance while preserving both safety and liveness.

1 Introduction
Current industry projections indicate that nonvolatile, byte-addressable memory
(NVM) will become commonplace over the next few years. While the availability
of NVM suggests the possibility of keeping persistent data in main memory (not
just in the file system), the fact that recent updates to registers and cache may be
lost during a power failure means that the data in main memory, if not carefully
managed, may not be consistent at recovery time.

Maintaining a consistent state in NVM requires special care to order main
memory updates. Several groups have designed libraries to support such ordering
using failure atomic updates, via either a transactional memory inter-
face [6,7,20,26] or one inferred from mutex synchronization [5,17]. Others

Fig. 1. Linearization bounds for interrupted operations under thread reuse failure model. Displayed is a concurrent abstract (operation-level) history of two threads ($T_1$ and $T_2$) on two objects ($O_1$ and $O_2$); linearization points are shown as circles. These correctness conditions differ in the deadline for linearization for a pending operation interrupted by a crash ($T_1$’s first operation). Strict linearizability [1] requires that the pending operation linearizes or aborts by the crash. Persistent atomicity [10] requires that the operation linearizes or aborts before any subsequent invocation by the pending thread on any object. Recoverable linearizability [2] requires that the operation linearizes or aborts before any subsequent linearization by the pending thread on that same object; under this condition a thread may have more than one operation pending at a time. $O_2$ demonstrates the non-locality of persistent atomicity; $T_2$ demonstrates a program order inversion under recoverable linearizability.

have designed data structures that tolerate power failures (e.g. [25, 27]), but the semantics of these structures are typically specified informally; the criteria according to which they are correct remain unclear. Guerraoui and Levy have proposed persistent atomicity [10] as a safety condition for persistent concurrent objects. This condition ensures that the state of an object will be consistent in the wake of a crash, but it does not provide locality: correct histories of separate objects, when merged, will not necessarily yield a correct composite history. Berryhill et al. have proposed an alternative, recoverable linearizability [2], which achieves locality but may sacrifice program order after a crash. Earlier work by Aguilera and Frøhland proposed strict linearizability [1], which preserves both locality and program order but provably precludes the implementation of some wait-free objects for certain (limited) machine models. These safety conditions are illustrated in Fig. 1.

Interestingly, both the lack of locality in persistent atomicity and the loss of program order in recoverable linearizability stem from the assumption that an individual abstract thread may crash, recover, and then continue execution. While well defined, this failure model is more general than is normally assumed in real-world systems. More commonly, processes are assumed to fail together, as part of a “full system” crash. A data structure that survives such a crash may safely assume that subsequent accesses will be performed by different threads. We observe that if we consider only full-system crashes (an assumption modeled as a well-formedness constraint on histories), then persistent atomicity and recoverable linearizability are indistinguishable (and thus local). They are also satisfied by existing persistent structures. We use the term durable linearizability to refer to this merged safety condition under the restricted failure model.
Independent of failure model, existing theoretical work typically requires that operations become persistent before they return to their caller. In practice, this requirement is likely to impose unacceptable overhead, since persistent memory, while dramatically faster than disk or flash storage, still incurs latencies of hundreds of cycles. To address the latency problem, we introduce buffered durable linearizability, which requires only that an operation be “persistently ordered” before it returns. State in the wake of a crash is still required to be consistent, but it need not necessarily be fully up-to-date. Data structures designed with buffering in mind will typically provide an explicit sync method that guarantees, upon its return, that all previously ordered operations have reached persistent memory; an application thread might invoke this method before performing I/O. Unlike its unbuffered variant, buffered durable linearizability is not local: a history may fail to be buffered durably linearizable even if all of its object subhistories are. If the buffering mechanism is shared across all objects, however, an implementation can ensure that all realizable histories—those that actually emerge from the implementation—will indeed be buffered durably linearizable: the post-crash states of all objects will be mutually consistent.

At the implementation level, prior work has explored the memory persistency model (analogous to a traditional consistency model) that governs instructions used to push the contents of cache to NVM. Existing persistency models assume that hardware will track dependencies and automatically write dirty cache lines back to NVM as necessary [8, 19, 23]. Unfortunately, real-world ISAs require the programmer to request writes-back explicitly. Furthermore, existing persistency models have been explored only for sequentially consistent (SC) [23] or total-store order (TSO) machines [8, 19]. At the same time, recent persistency models [19, 23] envision functionality not yet supported by commercial ISAs—namely, hardware buffering in an ordered queue of writes-back to persistent memory, allowing persistence fence (pfence) ordering instructions to complete without waiting for confirmation from the physical memory device. To accommodate anticipated hardware, we introduce a memory persistency model, explicit epoch persistency, that is both buffered and fully relaxed (release consistent).

Just as traditional concurrent objects require not only safety but liveness, so too should persistent objects. We define two optional liveness conditions: First, an object designed for buffered durable linearizability may provide nonblocking sync, ensuring that calls to sync complete without blocking. Second, a nonblocking object may provide bounded completion, limiting the amount of work done after a crash prior to the completion (if any) of operations interrupted by the crash. As a liveness constraint, bounded completion contrasts with prior art which imposes safety constraints [1, 2, 10] on completion (see Fig. 1).

We also present a simple transform that takes a data-race-free program designed for release consistency and generates an equivalent program in which the state persisted at a crash is guaranteed to represent a consistent cut across the happens-before order of the original program. When the original program comprises the implementation of a linearizable nonblocking concurrent object, extensions to this transform result in a buffered durably or durably linearizable
object. (If the original program is blocking, additional machinery—e.g., undo logging—may be required. While we do not consider such machinery here, we note that it still requires consistency as a foundation.)

To enable reasoning about our correctness conditions, we extend the notion of linearization points into persistent memory objects, and demonstrate how such persist points can be used to argue a given implementation is correct. We also consider optimizations (e.g. elimination) that may safely be excluded from persistence in order to improve performance. Proofs for our lemmas and theorems can be found in an associated technical report [18].

2 Abstract Models

An abstract history is a sequence of events, which can be: (i) invocations of an object method, (ii) responses associated with invocations, and (iii) system-wide crashes. We use $O.inv(m)_t(params)$ to denote the invocation of operation $m$ on object $O$, performed by thread $t$ with parameters $params$. Similarly, $O.res(m)_t(retvals)$ denotes the response of $m$ on $O$, again performed by $t$, returning $retvals$. A crash is denoted by $C$.

Given a history $\mathcal{H}$, we use $\mathcal{H}[t]$ to denote the subhistory of $\mathcal{H}$ containing all and only the events performed by thread $t$. Similarly, $\mathcal{H}[O]$ denotes the subhistory containing all and only the events performed on object $O$, plus crash events. We use $C_i$ to denote the $i$-th crash event, and $\text{ops}(\mathcal{H})$ to denote the subhistory containing all events other than crashes. The crash events partition a history as $\mathcal{H} = E_0 C_1 E_1 C_2 \ldots E_{c-1} C_c E_c$, where $c$ is the number of crash events in $\mathcal{H}$. Note that $\text{ops}(E_i) = E_i$ for all $0 \leq i \leq c$. We call the subhistory $E_i$ the $i$-th era of $\mathcal{H}$.

Given a history $\mathcal{H} = \mathcal{H}_1 A \mathcal{H}_2 B \mathcal{H}_3$, where $A$ and $B$ are events, we say that $A$ precedes $B$ (resp. $B$ succeeds $A$). For any invocation $I = O.inv(m)_t(params)$ in $\mathcal{H}$, the first $R = O.res(m)_t(retvals)$ (if any) that succeeds $I$ in $\mathcal{H}$ is called a matching response. A history $S$ is sequential if $S = I_0 R_0 \ldots I_x R_x$ or $S = I_0 R_0 \ldots I_x R_x I_{x+1}$, for $x \geq 0$, and $\forall 0 \leq i \leq x, R_i$ is a matching response for $I_i$.

**Definition 1 (Abstract Well-Formedness).** An abstract history $\mathcal{H}$ is said to be well formed if and only if $\mathcal{H}[t]$ is sequential for every thread $t$.

Note that sequential histories contain no crash events, so the events of a given thread are confined to a single era. (In practice, thread IDs may be re-used as soon as operations of the previous era have completed. In particular, an object with bounded completion [Sect. 3.3, Definition 10] can rapidly reuse IDs.)

We consider only well-formed abstract histories. A completed operation in $\mathcal{H}$ is any pair $(I, R)$ of invocation $I$ and matching response $R$. A pending operation in $\mathcal{H}$ is any pair $(I, \bot)$ where $I$ has no matching response in $\mathcal{H}$. In this case, $I$ is called a pending invocation in $\mathcal{H}$, and any response $R$ such that $(I, R)$ is a completed operation in $\mathcal{H}$ is called a completing response for $\mathcal{H}$.

**Definition 2 (Abstract Happens-Before).** In any (well-formed) abstract history $\mathcal{H}$ containing events $E_1$ and $E_2$, we say that $E_1$ happens before $E_2$
(denoted \( E_1 \prec E_2 \)) if \( E_1 \) precedes \( E_2 \) in \( \mathcal{H} \) and (1) \( E_1 \) is a crash, (2) \( E_2 \) is a crash, (3) \( E_1 \) is a response and \( E_2 \) is an invocation, or (4) there exists an event \( \bar{E} \) such that \( E_1 < \bar{E} \prec E_2 \). We extend the order to operations: \((I_1, R_1) \prec (I_2, x)\) if and only if \( R_1 \prec I_2 \).

Two histories \( \mathcal{H} \) and \( \mathcal{H}' \) are said to be equivalent if \( \mathcal{H}[t] = \mathcal{H}'[t] \) for every thread \( t \). We use \( \text{compl}(\mathcal{H}) \) to denote the set of histories that can be generated from \( \mathcal{H} \) by appending completing responses, and \( \text{trunc}(\mathcal{H}) \) to denote the set of histories that can be generated from \( \mathcal{H} \) by removing pending invocations. As is standard, a history \( \mathcal{H} \) is linearizable if it is well formed, it has no crash events, and there exists some history \( \mathcal{H}' \in \text{trunc}(\text{compl}(\mathcal{H})) \) and some legal sequential history \( \mathcal{S} \) equivalent to \( \mathcal{H}' \) such that \( \forall E_1, E_2 \in \mathcal{H}' \ [E_1 \prec_{\mathcal{H}} E_2 \Rightarrow E_1 \prec_{\mathcal{S}} E_2] \).

**Definition 3 (Durable Linearizability).** An abstract history \( \mathcal{H} \) is said to be durably linearizable if it is well formed and \( \text{ops}(\mathcal{H}) \) is linearizable.

Durable linearizability captures the idea that operations become persistent before they return; that is, if a crash happens, all previously completed operations remain completed, with their effects visible. Operations that have not completed as of a crash may or may not be completed in some subsequent era. Intuitively, their effects may be visible simply because they “executed far enough” prior to the crash (despite the lack of a response), or because threads in subsequent eras finished their execution for them (for instance, by scanning an “announcement array” in the style of universal constructions [15]). While this approach is simple, it preserves important properties from linearizability, namely locality (composability) and nonblocking progress [18].

Given a history \( \mathcal{H} \) and any transitive order \( \prec \) on events of \( \mathcal{H} \), a \( \prec \)-consistent cut of \( \mathcal{H} \) is a subhistory \( \mathcal{P} \) of \( \mathcal{H} \) where if \( E \in \mathcal{P} \) and \( E' \prec E \) in \( \mathcal{H} \), then \( E' \in \mathcal{P} \) and \( E' \prec E \) in \( \mathcal{P} \). In abstract histories, we are often interested in cuts consistent with \( \prec \), the happens-before order on events.

**Definition 4 (Buffered Durable Linearizability).** A history \( \mathcal{H} \) with \( c \) crash events is said to be buffered durably linearizable if it is well formed and there exist subhistories \( \mathcal{P}_0, \ldots, \mathcal{P}_{c-1} \) such that for all \( 0 \leq i \leq c \), \( \mathcal{P}_i \) is a \( \prec \)-consistent cut of \( \mathcal{E}_i \), and \( \mathcal{P} = \mathcal{P}_0 \ldots \mathcal{P}_{i-1} \mathcal{E}_i \) is linearizable.

The intent here is that events in the portion of \( \mathcal{E}_i \) after \( \mathcal{P}_i \) were buffered but failed to persist before the crash. Note that since \( \mathcal{P}_i = \mathcal{E}_i \) is a valid \( \prec \)-consistent cut for all \( 0 \leq i < c \), we can have \( \mathcal{P} = \text{ops}(\mathcal{H}) \), and therefore any durably linearizable history is buffered durably linearizable. Note also that buffered durable linearizability is not in general local: if an operation does not persist before it returns, we will not in general be able to ensure that it persists before any operation that follows it in happens-before order unless we arrange for the implementations of separate objects to cooperate.

### 3 Concrete Models

Concurrent objects are typically implemented by code in some computer language. We want to know if this code is correct. Following standard practice, we
model implementation behavior as a set of concrete histories, generated under some language and machine model assumed to be specified elsewhere. Each concrete history consists of a sequence of events, including not only operation invocations, responses, and crash events, but also load, store, and read-modify-write (RMW—e.g., compare-and-swap [CAS]) events, which access the representation of the object. Let $x.\text{ld}_t(v)$ denote a load of variable $x$ by thread $t$, returning the value $v$. Let $x.\text{st}_t(v)$ denote a store of $v$ to $x$ by $t$.

Given a concrete history $\mathcal{H}$, the abstract history of $\mathcal{H}$, denoted $\text{abstract}(\mathcal{H})$, is obtained by eliding all events other than invocations, responses, and crashes. As in abstract histories, we use $\mathcal{H}[t]$ and $\mathcal{H}[O]$ to denote the thread and object subhistories of $\mathcal{H}$. The concept of era from Sect. 2 applies verbatim. We say that an event $E$ lies between events $A$ and $B$ in a concrete or abstract history $\mathcal{H}$ if $A$ precedes $E$ and $E$ precedes $B$ in $\mathcal{H}$.

**Definition 5 (Concrete Well-Formedness).** A concrete history $\mathcal{H}$ is well-formed if and only if

1. $\text{abstract}(\mathcal{H})$ is well-formed.
2. In each thread subhistory of $\mathcal{H}$, each memory event either (a) lies between some invocation and its matching response; (b) lies between a pending invocation $I$ and the first crash that succeeds $I$ in $\mathcal{H}$ (if such a crash exists); (c) succeeds a pending invocation $I$ if no crash succeeds $I$ in $\mathcal{H}$.
3. The values returned by the loads and RMWs respect the reads-see-writes relation (Definition 7, below).

### 3.1 Basic Memory Model

For the sake of generality, we build our reads-see-writes relation on the highly relaxed release consistency memory model [9]. We allow certain loads to be labeled as load-acquire ($\text{ld.acq}$) events and certain stores to be labeled as store-release ($\text{st.rel}$) events. We treat RMW events as atomic ($\text{ld.acq}, \text{st.rel}$) pairs.

**Definition 6 (Concrete Happens-Before).** Given events $E_1$ and $E_2$ of concrete history $\mathcal{H}$, we say that $E_1$ is sequenced-before $E_2$ if $E_1$ precedes $E_2$ in $\mathcal{H}[t]$ for some thread $t$ and (a) $E_1$ is a $\text{ld.acq}$, (b) $E_2$ is a $\text{st.rel}$, or (c) $E_1$ and $E_2$ access the same location. We say that $E_1$ synchronizes-with $E_2$ if $E_2 = x.\text{ld.acq}_t(v)$ and $E_1$ is the closest preceding $x.\text{st.rel}_t(v)$ in history order. The happens-before partial order on events in $\mathcal{H}$ is the transitive closure of sequenced-before order with synchronizes-with order. As in abstract histories, we write $E_1 \prec E_2$.

Note that the definitions of happens-before are different for concrete and abstract histories; which one is meant in a given case should be clear from context.

The release-consistent model corresponds closely to that of the ARM v8 instruction set and can be considered a generalization of Intel's x86 instruction set. Given concrete happens-before, we can define the reads-see-writes relation:
Definition 7 (Reads-See-Writes). A concrete history $H$ respects the reads-
see-writes relation if for each load $R \in \{x.\text{ld}_t(v), x.\text{ld}_{\text{acq}}(v)\}$, there exists a
store $W \in \{x.\text{st}_u(v), x.\text{st}_{\text{rel}}(v)\}$ such that either (1) $W \prec R$ and there exists
no store $W'$ of $x$ such that $W \prec W' \prec R$ or (2) $W$ is unordered with respect to
$R$ under happens-before.

For simplicity of exposition, we consider the initial value of each variable to
have been specified by a store that happens before all other instructions in the
history. We consider only well-formed concrete histories in this paper. If case (2)
in Definition 7 never occurs in a history $H$, we say that $H$ is data-race-free.

3.2 Extensions for Persistence

The semantics of instructions controlling the ordering and timing under which
cached values are pushed to persistent memory comprise a memory persist-
tency model [23]. Since any machine with bounded caches must sometimes evict
and write back a line without program intervention, the principal challenge for
designers of persistent objects is to ensure that a newer write does not persist
before an older write (to some other location) when correctness after a crash
requires the locations to be mutually consistent.

Under the epoch persistency model of Condit et al. [8] and Pelley et al. [23],
writes-back to persistent memory (persist operations) are implicit—they do not
appear in the program's instruction stream. When ordering is required, a pro-
gram can issue a special instruction (which we call a pfence) to force all of its
earlier writes to persist before any subsequent writes. Periods between pfences in
a given thread are known as epochs. As noted by Pelley et al. [23], it is possible
for writes-back to be buffered. When necessary, a separate instruction (which we
call psync) can be used to wait until the buffer has drained.

Unfortunately, implicit write-back of persistent memory is difficult to imple-
ment in real hardware [8,19,23]. Instead, manufacturers have introduced explicit
persistent write-back (pwb) instructions. These are typically implemented in an
eager fashion: a pwb starts the write-back process; a psync waits for the comple-
tion of all prior pwbs (under some appropriate definition of “prior”).

We generalize proposed implicit persistency models [8,19,23] and real world
(explicit) persistency ISAs to define our own, new model, which we call explicit
epoch persistency. Like real-world explicit ISAs, our persistency model requires
programmers to use a pwb to force back data into persistence. Like other buffered
models, we provide pfence, which ensures that all previous pwbs are ordered
with respect to any subsequent pwbs, and psync, which waits until all previous
pwbs have actually reached persistent memory. We assume that persists to a
given location respect coherence: the programmer need never worry that a newly
persisted value will later be overwritten by the write-back of some earlier value.
Unlike prior art, which assumes sequential consistency [23] or total store order [8,
19,20], we integrate our instructions into a relaxed (release consistent) model.

Returning to concrete histories, we use $x.pwb_t$ to denote a pwb of variable
$x$ by thread $t$, pfence$_t$ to denote a pfence by thread $t$, and psync$_t$ to denote a
psync by thread \( t \). We amend our definition of concrete histories to include these persistence events. We refer to any non-crash event of a concrete history as an instruction.

**Definition 8 (Persist Ordering).** Given events \( E_1 \) and \( E_2 \) of concrete history \( \mathcal{H} \), with \( E_1 \) preceding \( E_2 \) in the same thread subhistory, we say that \( E_1 \) is persist-ordered before \( E_2 \), denoted \( E_1 \ll E_2 \), if

(a) \( E_1 = \text{pwb} \) and \( E_2 \in \{ \text{pfence, psync} \} \);
(b) \( E_1 \in \{ \text{pfence, psync} \} \) and \( E_2 \in \{ \text{pwb, st, st_rel} \} \);
(c) \( E_1, E_2 \in \{ \text{st, st_rel, pwb} \} \), and \( E_1 \) and \( E_2 \) access the same location;
(d) \( E_1 \in \{ \text{id, ld_acq} \} \), \( E_2 = \text{pwb} \), and \( E_1 \) and \( E_2 \) access the same location; or
(e) \( E_1 = \text{ld_acq} \) and \( E_2 \in \{ \text{pfence, psync} \} \).

Finally, across threads, \( E_1 \ll E_2 \) if

(f) \( E_1 = \text{st_rel} \), \( E_2 = \text{id_acq} \), and \( E_1 \) synchronizes with \( E_2 \).

To identify the values available after a crash, we extend the syntax of concrete histories to allow store events to be labeled as “persisted,” meaning that they will be available in subsequent eras if not overwritten. Persisted store labels introduce additional well-formedness constraints:

**Definition 9 (Concrete Well-Formedness [augments Definition 5]).** A concrete history \( \mathcal{H} \) is well-formed if and only if it satisfies the properties of Definition 5 and

4. For each variable \( x \), at most one store of \( x \) is labeled as persisted in any given era. We say the \((x,0)\)-persisted store is the labeled store of \( x \) in \( \mathcal{E}_0 \), if there is one; otherwise it is the initialization store of \( x \). For \( i > 0 \), we say the \((x,i)\)-persisted store is the labeled store of \( x \) in \( \mathcal{E}_i \), if there is one; otherwise it is the \((x,i-1)\)-persisted store.
5. For any \((x,i)\)-persisted store \( W \), there is no store \( W' \) of \( x \) and psync event \( P \) such that \( W \ll W' \ll P \).
6. For any \((x,i)\)-persisted store \( W \), there is no store \( W' \) of \( x \) and \((y,i)\)-persisted store \( S \) such that \( W \ll W' \ll S \).

These rules ensure that persisted stores compose a \( \ll \)-consistent cut of \( \mathcal{H} \). To allow loads to see persisted values in the wake of a crash, we augment the definition of happens-before to declare that the \((x,i)\)-persisted store happens before all events of era \( \mathcal{E}_{i+1} \). Definition 7 then stands as originally written.

### 3.3 Liveness

With strict linearizability, no operation is left pending in the wake of a crash: either it has completed when execution resumes, or it never will. With persistent atomicity and recoverable linearizability, the time it may take to complete a pending operation \( m \) in thread \( t \) can be expressed in terms of execution steps in \( t \)'s reincarnation (see Fig.1). With durable linearizability, which admits no reincarnated threads, any bound on the time it may take to complete \( m \) must depend on other threads.
Definition 10 (Bounded Completion). An object $O$ has bounded completion if, for each concrete history $\mathcal{H}$ of $O$ that ends in a crash with an operation $m$ on $O$ still pending, there exists a positive integer $k$ such that for all realizable extensions $\mathcal{H}'$ of $\mathcal{H}$ in which some era of $\mathcal{H}' \setminus \mathcal{H}$ contains at least $k$ instructions issued by an arbitrary thread, either (1) for all realizable extensions $\mathcal{H}''$ of $\mathcal{H}'$, $\mathcal{H}'' \setminus \text{inv}(m)$ is buffered durably linearizable or (2) for all realizable extensions $\mathcal{H}''$ of $\mathcal{H}'$, if there exists a completed operation $n$ with $\text{inv}(n) \in \mathcal{H}'' \setminus \mathcal{H}'$, then there exists a sequential history $S$ equivalent to $\mathcal{H}''$ with $m \prec_S n$.

Briefly: by $k$ post-crash instructions by any thread, $m$ completes, if it ever will.

It is also desirable to discuss progress towards persistence. Under durable linearizability, every operation persists before it responds, so any liveness property (e.g., lock freedom) that holds for method invocations also holds for persistence. Under buffered durable linearizability, the liveness of persist ordering is subsumed in method invocations.

As noted in Sect. 1, data structures for buffered persistence will typically need to provide a sync method that guarantees, upon its return, that all previously ordered operations have reached persistent memory. If sync is not rolled into operations, then buffering (and sync) need to be coordinated across all mutually consistent objects, for the same reason that buffered durable linearizability is not a local property (Sect. 2). The existence of sync impacts the definition of buffered durable linearizability. In Definition 4, all abstract events that precede a sync instruction in their era must appear in $P$, the sequence of consistent cuts. For a set of nonblocking objects, it is desirable that the shared sync method be wait-free or at least obstruction free—a property we call nonblocking sync. (As sync is shared, lock freedom doesn’t seem applicable.)

4 Implementations

Given our prior model definitions and correctness conditions, we present an automated transform that takes as input a concurrent multi-object program written for release consistency and transient memory, and turns it into an equivalent program for explicit epoch persistency. Rules (T1) through (T5) of our transform (below) preserve the happens-before ordering of the original concurrent program: in the event of a crash, the values present in persistent memory are guaranteed to represent a $\prec$-consistent cut of the pre-crash history. Additional rules (T6) through (T8) serve to preserve real-time ordering not captured by happens-before but required for durable linearizability. The intuition behind our transform is that, for nonblocking concurrent objects, a cut across the happens-before ordering represents a valid static state of the object [22]. For blocking objects, additional recovery mechanisms (not discussed here) may be needed to move the cut if it interrupts a failure-atomic or critical section [5, 7, 17, 26].

The following rules serve to preserve happens-before ordering into persist-before ordering. Their key observation is that a thread $t$ which issues a $x.\text{st.rel}_t(v)$ cannot atomically ensure the value’s persistence. Thus, the subsequent thread $u$ which synchronizes-with $x.\text{ld.acq}_u(v)$ shares responsibility for $x$’s persistence.
(T1) Immediately after \(x \cdot \text{st}_t(v)\), write back the value by issuing \(x \cdot \text{pwb}_t\).

(T2) Immediately before \(x \cdot \text{st}_t(v)\), issue a pfence; immediately afterward, write back the value by issuing \(x \cdot \text{pwb}_t\).

(T3) Immediately after \(x \cdot \text{ld}_t(v)\), write back the loaded value by issuing \(x \cdot \text{pwb}_t\), then issue a pfence.

(T4) Handle CAS instructions as atomic \((x \cdot \text{ld}_t(v), x \cdot \text{st}_t(v'))\) pairs: immediately before the pair, issue a pfence; immediately afterward, write back the (potentially modified) value by issuing \(x \cdot \text{pwb}_t\), then issue a pfence. (Extensions for other RMW instructions are straightforward.)

(T5) Take no persistence action on loads.

In the wake of a crash, the values present in persistent memory will reflect, by Definition 9, a consistent cut across the (partial) persist ordering \(<\) of the preceding era. We wish to show that in any program created by our transform, it will also reflect a consistent cut across that era’s happens-before ordering \(<\). Mirroring condition 6 of concrete well-formedness (Definition 9), but with \(<\) instead of \(<\), we can prove [18]:

**Lemma 1.** Consider a concrete history \(H\) emerging from our transform. For any location \(x\) and \((x, i)\)-persisted store \(A \in H\), there exists no store \(A'\) of \(x\), location \(y\), and \((y, i)\)-persisted store \(B \in H\) such that \(A < A' < B\).

Unfortunately, preservation of happens-before is not enough to give us durable linearizability: we also need to preserve the “real-time” order of non-overlapping operations (Definition 2, clause 3) in different threads. (As in conventional linearizability, “real time” serves as a stand-in for forms of causality—e.g., loads and stores of variables outside of operations—that are not captured in our histories.)

For objects that are (non-buffered) durably linearizable, we simply need to ensure that each operation persists before it returns:

(T6) Immediately before \(O \cdot \text{res}(m)_t\), issue a psync.

For buffered durably linearizable objects, we leave out the psync and instead introduce a shared global variable \(G\):

(T7) Immediately before \(O \cdot \text{res}(m)_t\), issue a pfence, then issue \(G \cdot \text{st}_t(g)\), for some arbitrary fixed value \(g\).

(T8) Immediately after \(O \cdot \text{inv}(m)_t\), issue \(G \cdot \text{ld}_t(g)\), for the same fixed value \(g\), then issue a pfence.

To facilitate our proof of correctness [18], we introduce the notion of an effective history for \(H\). This history leaves out both the crashes of \(H\) and, in each era, the suffix of each thread’s execution that fails to reach persistence before the crash. We can then prove (Lemma 2) that any effective history of a program emerging from our transform is itself a valid history of that program (and could have happened in the absence of crashes), and (Lemma 3) that the (crash-free) abstract history corresponding to the effective history is identical to
some concatenation of \(<\)-consistent cuts of the eras of the (crash-laden) abstract history corresponding to \(\mathcal{H}\). These two lemmas then support our main result (Theorem 1).

**Definition 11.** Consider a concrete history \(\mathcal{H} = E_0 C_1 \mathcal{E}_1 \ldots \mathcal{E}_{c-1} C_c \mathcal{E}_c\). For any thread \(t\) and era \(0 \leq i < c\), let \(E^t_i\) be the last store in \(\mathcal{E}_i[t]\) that either is a persisted store or happens before some persisted store in \(\mathcal{E}_i\). Let \(B^t_i\) be the last non-store instruction that succeeds \(E^t_i\) in \(\mathcal{E}_i[t]\), with no stores by \(t\) in-between (or, if there is no such instruction, \(E^t_i\) itself). Finally, for \(0 \leq j < c\), let \(\mathcal{P}_j\) be the subhistory of \(\mathcal{E}_j\) obtained by removing all persistence events and, for each \(t\), all events that follow \(B^t_j\) in \(\mathcal{E}_j[t]\). The effective concrete history of \(\mathcal{H}\) at era \(i\), denoted \(\text{effective}_i(\mathcal{H})\), is the history \(\mathcal{P}_0 \ldots \mathcal{P}_{i-1} \mathcal{E}_i\).

**Lemma 2.** Consider a nonblocking, data-race-free program \(\mathbb{P}\), and the transformed program \(\mathbb{P}'\). For any realizable concrete history \(\mathcal{H}\) of \(\mathbb{P}'\), and any \(0 \leq i \leq c\), \(\text{effective}_i(\mathcal{H})\) is a realizable concrete history of \(\mathbb{P}\).

**Lemma 3.** Consider a nonblocking, data-race-free program \(\mathbb{P}\), and the transformed program \(\mathbb{P}'\). For any realizable concrete history \(\mathcal{H}\) of \(\mathbb{P}'\), and any \(0 \leq i \leq c\), the history abstract(\(\text{effective}_i(\mathcal{H})\)) is precisely \(\mathcal{P}_0^a \ldots \mathcal{P}_{i-1}^a \mathcal{E}_i^a\), where \(\mathcal{E}_i^a\) is the \(i\)-th era of abstract(\(\mathcal{H}\)), and \(\mathcal{P}_i^a\) is a \(<\)-consistent cut of \(\mathcal{E}_i^a\).

**Theorem 1 (Buffered Durable Linearizability).** If a nonblocking, data-race-free program \(\mathbb{P}\) is linearizable, the transformed program \(\mathbb{P}'\) is buffered durably linearizable.

In addition to the correctness properties of our automated transform, we can characterize other properties of the code it generates. For example, the transformed implementation of a nonblocking concurrent object requires no change to persistent state before relaunching threads—that is, it has a null recovery procedure. Moreover, any set of transformed objects will share a wait-free sync method (a single call to \texttt{psync}).

In each operation on a transient linearizable concurrent object, we can identify some instruction within as the operation’s announce point: once execution reaches the announce point, the operation may linearize without its thread taking additional steps. Wait-free linearizable objects sometimes have announce points that are not atomic with their linearization points. In most nonblocking objects, however, the announce point is the linearization point, a property we call unannounced. This property results in stronger correctness properties in the persistent version when the object is transformed. The result of transform when applied to an object whose operations are unannounced is strictly linearizable. Perhaps surprisingly, our transform does not guarantee bounded completion, even on wait-free objects. Pending announced operations may be ignored for an arbitrary interval before eventually being helped to completion [4] [14, Sect. 4.2.5].
4.1 Persist Points

Linearizability proofs for transient objects are commonly based on the notion of a linearization point—an instruction between an operation’s invocation and response at which the operation appears to “take effect instantaneously” [16]. In simple objects, linearization points may be statically known. In more complicated cases, one may need to reason retrospectively over a history in order to identify the linearization points, and the linearization point of an operation need not necessarily be an instruction issued by the invoking thread.

The problem for persistent objects is that an operation cannot generally linearize and persist at the same instant. Clearly, it will need to linearize first; otherwise it will not know what values to persist. Unfortunately, as soon as an operation (call it \( m \)) linearizes, other operations can see its state, and might, naively, linearize and persist before \( m \) had a chance to persist. The key to avoiding this problem is for every operation \( n \) to ensure that any predecessor on which it depends has persisted (in the unbuffered case) or persist-ordered (with global buffering) before \( n \) itself linearizes. To preserve real-time order, \( n \) must also persist (or persist-order) before it returns.

**Theorem 2 (Persist Points).** Suppose that for each operation \( m \) of object \( O \) it is possible to identify not only a linearization point \( l_m \) between inv(\( m \)) and res(\( m \)) but also a persist point instruction \( p_m \) between \( l_m \) and res(\( m \)) such that (1) “all stores needed to capture \( m \)” are written back to persistent memory, and a fence issued, before \( p_m \); and (2) whenever operations \( m \) and \( n \) overlap, linearization points can be chosen such that either \( p_m \preceq l_n \) or \( l_n \) precedes \( l_m \). Then \( O \) is (buffered) durably linearizable.

The notion of “all stores needed to capture \( m \)” will depend on the details of \( O \). In simple cases (e.g., those emerging from our automated transform), those stores might be all of \( m \)’s updates to shared memory. In more optimized cases, they might be a proper subset (as discussed below). Generally, a nonblocking persistent object will embody helping: if an operation has linearized but not yet persisted, its successor operation must be prepared to push it to persistence.

4.2 Practical Applications

A variety of standard concurrent data structure techniques can be adapted to work with both durable and strict linearizability and their buffered variants. While our automated transform can be used to create correct persistent objects, judicious use of transient memory can often reduce the overhead of persistence without compromising correctness. For instance, announcement arrays [13] are a common idiom for wait-free helping mechanisms. Implementing a transient announcement array [2] while using our transform on the remainder of the object state will generally provide a (buffered) strictly linearizable persistent object.

Other data structure components may also be moved into transient memory. Elimination arrays [12] might be used on top of a durably or strictly linearizable data structure without compromising its correctness. The flat combining
technique [11] is also amenable to persistence. Combined operations can be built together and ordered to persistence with a single `pFence`, then linked into the main data structure with another, reducing `pFence` instructions per operation. A transient combining array will generally result in a strictly linearizable object; leaving it persistent memory results in a durably linearizable object.

Several library and run-time systems have already been designed to take advantage of NVM; many of these can be categorized by the presented correctness conditions. Strictly linearizable examples include trees [25, 27], file systems [8], and hash maps [24]. Buffered strictly linearizable data structures also exist [21], and some libraries explicitly enable their construction [3, 5]. Durably (but not strictly) linearizable data structures are a comparatively recent innovation [17].

5 Conclusion

This paper has presented a framework for reasoning about the correctness of persistent data structures, based on two key assumptions: full-system crashes at the level of abstract histories and explicit write-back and buffering at the level of concrete histories. For the former, we capture safety as (buffered) durable linearizability; for the latter, we capture anticipated real-world hardware with explicit epoch consistency, and observe that both buffering and persistence introduce new issues of liveness. Finally, we have presented both an automatic mechanism to transform a transient concurrent object into a correct equivalent object for explicit epoch persistency and a notion of persist points to facilitate reasoning for other, more optimized, persistent objects.
