

Nonmonotonic Inheritance Networks

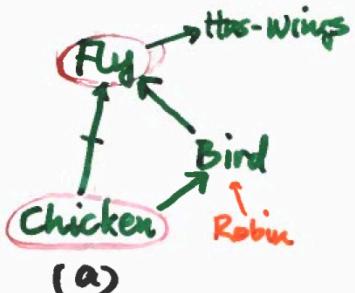

Show "normal" relationships among monadic predicates (sets).

e.g., Fly
 ↑
 Bird
 Birds normally fly
 (Most birds fly)

Mammal
 f
 Egg-layer
 Egg-layers normally are not mammals (Most egg-layers are non-mammals)

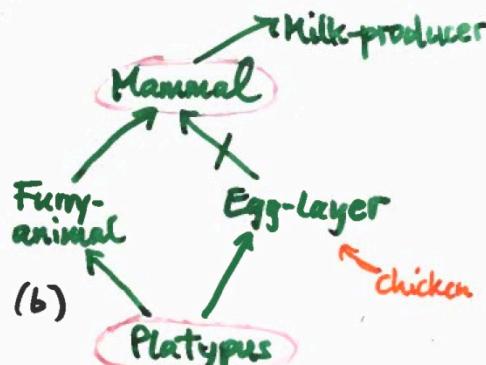

For the time being, we don't distinguish such "soft" (defeasible) relationships from strict ones (like $\text{Chicken} \rightarrow \text{Bird}$).

Two kinds of conflicts:

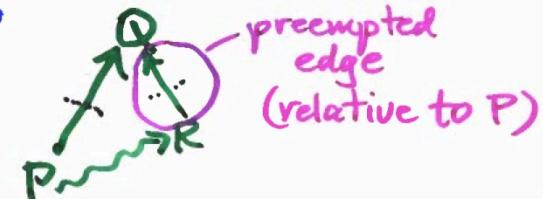

In (a), one feels that the $\text{chicken} \rightarrow \text{Fly}$ edge should "win" because it's more specific, i.e. chickens don't fly.

In (b), we can't really decide whether a platypus is or is not a mammal (unless we already know!).

This intuition can be captured with (what we'll call) the Triangle Rule:

A direct edge from P to Q preempts the final edge of any longer path from P to Q;
 (relative to P)

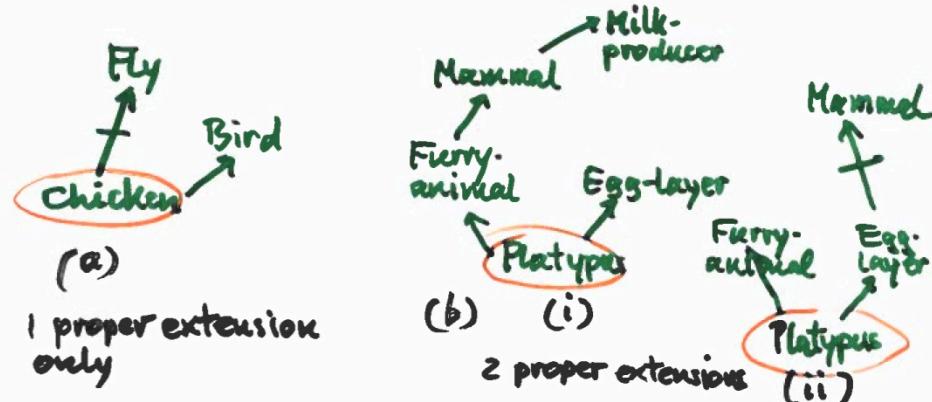

Reasoning

What can we infer from a given root node P, by tracing paths upward?
 Well, it depends on whether we're "credulous" or "skeptical".

Definition (informal):

- A proper extension of a node P in a NMI network (a directed, usually acyclic graph with positive & negative edges) is obtained by adding edges "bottom up" starting at P, subject to
 - never adding preempted edges (relative to a node already added); and
 - never adding both a positive edge and a negative edge entering the same node; and
 - never adding an edge from a node that has negative entering edges only.

E.g., the proper extensions of the previous example networks, relative to "chicken" and "Platypus" are:

Note: "Bottom-up" edge addition assumes that as many ancestors of a node Q as possible have been added before any edges to Q are added.*

Credulous reasoning (given a node P in a network)

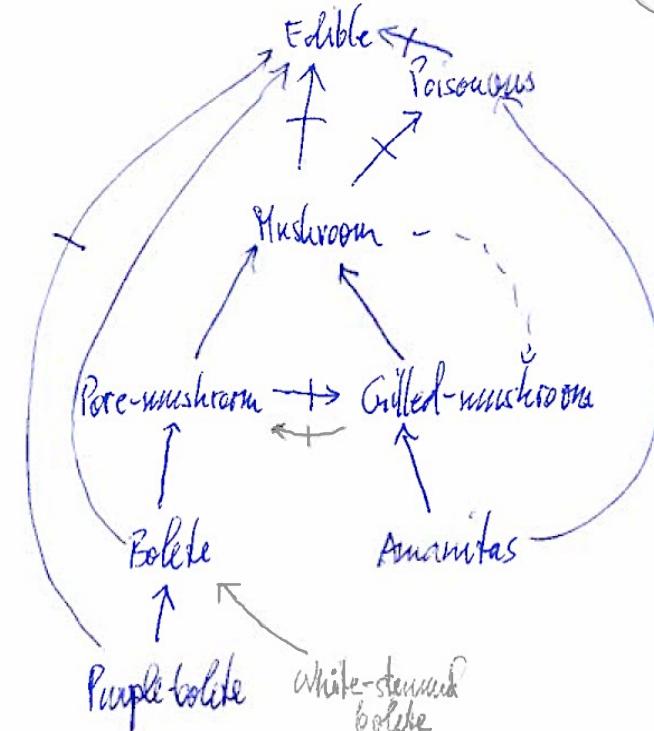

Pick any proper extension of P, & "believe" all conclusions reached from it.

Ideally skeptical reasoning

Believe the conclusions reached from P in all proper extensions.

E.g. All nodes in (a) above are believed, and only "Furry-animal" & "Egg-layer" are believed in (b), as conclusions from "Platypus".

* Also, we add all successor edges of a node that are not ruled out by (a), (b), or (c) (in the definition of proper extension) before adding any edges from any of the successors of the node.

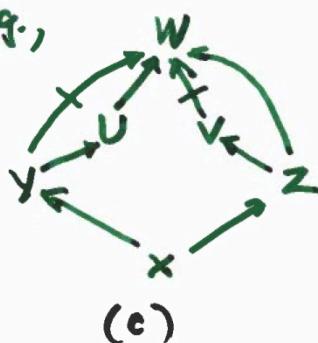

$A \rightarrow B$ does not entail $B \rightarrow A$

So we need to specify $B \dashv\vdash A$ separately

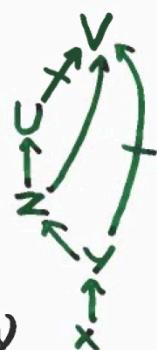

Acyclicity imposes severe constraints

Things can get a bit tricky ...

E.g.,

(c)

(d)

Caveat:

The B&L text doesn't use "proper" extensions, & defines "credulous" extensions differently.

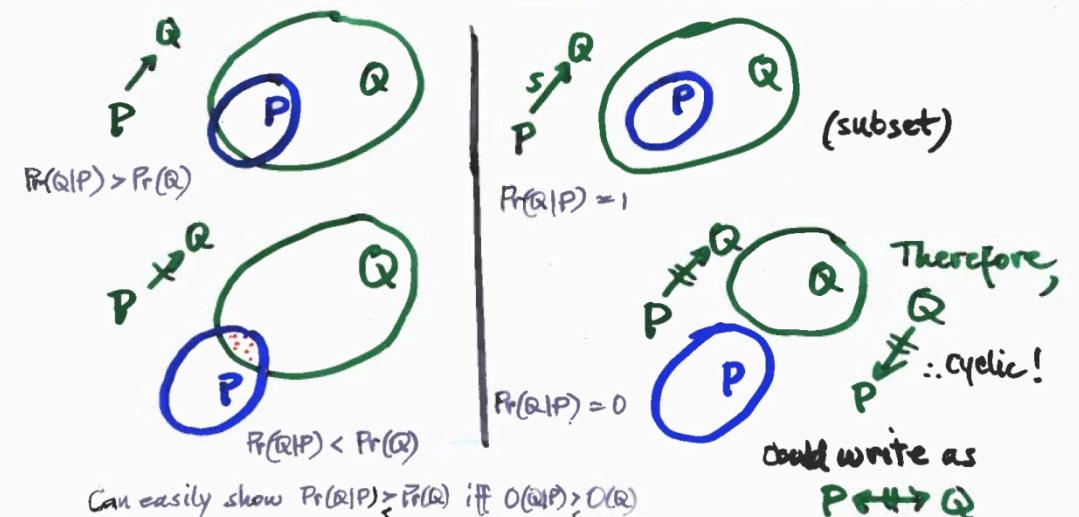

In (c), in forming a proper extension from X , we first add $Y, Z, U, \& V$. Then we can add either $Y \rightarrow W$ (but not $U \rightarrow W$), supporting $\neg W$; or we can add $Z \rightarrow W$ (but not $V \rightarrow W$), supporting W . So we have 2 credulous extensions, but only Y, Z, U, V are ideally skeptical conclusions.

In (d), it looks as if $Z \rightarrow V$ preempts $U \rightarrow V$; however, $Z \rightarrow V$ is itself preempted by $Y \rightarrow V$! But it doesn't matter, because $Y \rightarrow V$ also preempts $U \rightarrow V$. So the unique proper extension is

So in this case the credulous & ideally skeptical conclusions are the same: $Y, Z, U, \neg V$ are all believed as consequences of X .

A desirable distinction one can make (not in B&L):
Soft (defeasible) vs. strict (strong, hard) edges.

Can easily show $Pr(Q|P) > Pr(Q)$ iff $O(Q|P) > O(Q)$

In fact, allowing cycles seems potentially useful for cases like

We can then generalize the Triangle rule:

A strict path (of type $P_1 \xrightarrow{s} P_2 \xrightarrow{s} \dots \xrightarrow{s} P_n \xrightarrow{s} Q$, or of type $P_1 \xrightarrow{s} P_2 \xrightarrow{s} \dots \xrightarrow{s} P_n \dashv Q$) preempts the last edge of any other path of length ≥ 2 from P_i to Q .

Final comments: It would be better if we could take account of probabilities (if known); and if we allowed for multiple-premise rules, n-ary pred's, etc!
